Abstract

Land-use change is the single biggest driver of biodiversity loss in the tropics. Biodiversity models can be useful tools to inform policy-makers and conservationists of the likely response of species to anthropogenic pressures, including land-use change. However, such models generalize biodiversity responses across wide areas and many taxa, potentially missing important characteristics of particular sites or clades. Comparisons of biodiversity models with independently collected field data can help us understand the local factors that mediate broad-scale responses.

We collected independent bird occurrence and abundance data along two elevational transects in Mount Kilimanjaro, Tanzania and the Taita Hills, Kenya. We estimated the local response to land use and compared our estimates with modelled local responses based on a large database of many different taxa across Africa. To identify the local factors mediating responses to land use, we compared environmental and species assemblage information between sites in the independent and African-wide data sets.

Bird species richness and abundance responses to land use in the independent data followed similar trends as suggested by the African-wide biodiversity model, however the land-use classification was too coarse to capture fully the variability introduced by local agricultural management practices. A comparison of

¹ Current address: School of Life Science, University of Sussex, Brighton, United Kingdom, BN1 9RH: m.jung@sussex.ac.uk

assemblage characteristics showed that the sites on Kilimanjaro and the Taita Hills had higher proportions of forest specialists in croplands compared to the Africa-wide average. Local human population density, forest cover and vegetation greenness also differed significantly between the independent and Africa-wide datasets. Biodiversity models including those variables performed better, particularly in croplands, but still could not accurately predict the magnitude of local species responses to most land uses, probably because local features of the land management are still missed.

Overall, our study demonstrates that local factors mediate biodiversity responses to land use and cautions against applying biodiversity models to local contexts without prior knowledge of which factors are locally relevant.

47
Introduction

48
Humanity drives global biodiversity decline in many different ways (Butchart et al. 2010). Among the different
49
pressures, anthropogenic land-use change has been shown to have the most severe impact on terrestrial biodiversity
50
(Foley et al. 2005; Jetz et al. 2007; Gibson et al. 2011). A change in land use might greatly reduce the amount or quality
51
of habitat available to species, or contribute to landscape fragmentation resulting in declining species abundance and/or
52
local extinctions (Brooks et al. 2002). Therefore it is of particular interest to understand how assemblages of species
53
respond to land use, and if they can persist in a human-modified landscape (Gardner et al. 2007). Statistical biodiversity
54
models are increasingly applied over broad extents to predict the response of species assemblages to land use (Loh et al.
55
2005; Scholes and Biggs 2005; Alkemade et al. 2009; Newbold et al. 2014a; Newbold et al. 2015). Such models can be
56
based on data from many different taxonomic groups, and can inform policy-makers about biodiversity trends and
57
influence ongoing international debates about relevant mitigation schemes (Pereira et al. 2010; Leadley et al. 2014;
58
CBD 2014). However, in generalising across a wide area, such models likely miss local factors that mediate species’
59
response to land use.

60
Most biodiversity models employ a coarse land-use classification scheme (eg. Scholes and Biggs 2005;
61
Alkemade et al. 2009; Newbold et al. 2014a; Newbold et al. 2015) that cannot capture the full variability of local land-
62
use systems, often missing important land-use categories such as agroforestry (Scholes and Biggs 2005; Newbold et al.
63
2015). Others ignore the differential responses of taxonomic groups (Alkemade et al. 2009), which can be important
64
(e.g., Gibson et al. 2011; Murphy and Romanuk 2014; Newbold et al. 2014a). Some biodiversity models of local species
65
richness and abundance have found environmental variables such as land-use intensity, human population density and
66
metrics derived from vegetation-greenness data to be influential (Newbold et al. 2014a; De Palma et al. 2015). It is
67
however unclear if the inclusion of these variables is relevant in understanding how the local environment mediates
68
biodiversity responses to land use. Similarly it has been shown that functional characteristics can help explain species’
69
varying responses to land use on a broad scale (Owens and Bennett 2000; Flynn et al. 2009; Newbold et al. 2013; De
70
Palma et al. 2015), but to our knowledge no previous studies have evaluated whether those responses are consistent in a
71
local context. Comparing estimates derived from biodiversity models with local independent data, where the detailed
72
environmental conditions are known and taken into account, could help to identify some of the important local factors
73
that mediate biodiversity responses to land use and ultimately provide insight on how to improve the applicability of
74
biodiversity models.

Addressing the question of how biodiversity responds to land use is especially important in sub-Saharan Africa, where the congruent and patchy distribution of both biodiversity and human population leads to a high risk of biodiversity loss (Balmford et al. 2001; Burgess et al. 2007a; Pfeifer et al. 2012). In this study we investigated biodiversity responses to land use in two study areas in east Africa each with different geological, evolutionary and land-use history. We explicitly test if (1) the response of avian diversity to land use is different in those study areas compared to a taxonomically and geographically broad Africa-wide model of local biodiversity responses to land use, (2) investigate potential explanations for any mismatches using remote-sensed data and information on species' ecological characteristics and threat status, to identify the local factors that mediate the local response of biodiversity to land use; and (3) make recommendations for additional factors to be included in biodiversity models and sampling choices for biodiversity surveys.

Methods

Assemblage composition data

To generate African-wide estimates of how local species richness and abundance respond to land use, we used the database of the **Projecting Responses of Ecological Diversity In Changing Terrestrial Systems (PREDICTS)** project (Hudson et al. 2014; www.predicts.org.uk). While these data cover a broad extent, each individual sampling location covered only a small scale (of comparable grain-size to our independent data – see below). We used only the data sources for Africa (extracted 28/07/2014, see Table SI 1) with land use in each site classified as primary vegetation (1285 sites), secondary vegetation (485), plantation forest (441), cropland (612) and urban (33) habitat (see Hudson et al. 2014 for definitions). Note that 'urban' land use referred to all areas of human settlement, including rural villages. Additionally, we also used the information on land-use intensity according to the classification developed by the PREDICTS Project, which combines information on management intensity and proportion of each site impacted (SI Table 2; Hudson et al. 2014). This classification was used so that different land uses could be compared across the different studies, both in the African-wide dataset and the independent field data, and necessarily means that some of the variability in land-use systems is omitted.

We collected independent field data for birds (herein called 'independent data') along two transects on the southern slopes of Mount Kilimanjaro, Tanzania and the Taita Hills, Kenya (Figure 1). Both landscapes are known for their long history of human modification (Conte 2010; Heckmann et al. 2014), while having a contrasting geological age (~ 30 mil. years for Taita compared to ~2 mil. years for Kilimanjaro, see Platts et al. 2011), and each has different sets of endemic species (Hemp 2006a; Burgess et al. 2007b). Data on bird species richness and abundance were

1 105 collected visually and audibly using standardized 10-minute fixed-time point counts (Bibby et al. 2000), of 50-m radius,
2 106 along each of the transects. While more accurate estimates of biodiversity can be obtained by taking into account
3 107 detection probability (Buckland et al. 2008), our sampling methodology was chosen to match the sampling scheme of
4 108 bird studies in the PREDICTS database. Because detectability is likely to be higher in more open habitats, which are
5 109 often those with higher human land-use activity, our estimates of the effects of human land use on biodiversity (from
6 110 both the African-wide and independent datasets) are likely to be conservative. Point counts (N=147) were located along
7 111 the two transects to represent the land uses in the African-wide dataset, and were visited twice between March and May
8 112 2014. Sites were spread across a wide elevational range in both transects (836-2142 m on Taita and 715-1735 m on
9 113 Kilimanjaro). Some land use types could only be sampled in particular elevational ranges. For example, primary
10 114 vegetation only occurs in high elevations on both transects (Figure 1, Figure S4-D). Our survey captured local diversity
11 115 with total sampling effort comparable to similar studies in the African-wide dataset (24 hours on Kilimanjaro and 25
12 116 hours on Taita Hills, compared with an average of 35.15 ± 15.92 (SD) sampling hours in the African-wide dataset).
13 117 Seasonal changes in the abundance of certain bird species might introduce bias into our field study; however, a resurvey
14 118 of some of the sites in the Taita Hills in a different climatic season showed similar responses of avian diversity to land
15 119 use (Norfolk et al. in press). Species identity was determined following commonly used visual taxonomic guides and
16 120 assisted by audio recordings from freely available bird-sound databases (Stevenson and Fanshawe 2004;
17 121 <http://www.xeno-canto.org>). In total, 172 different bird species were observed at 147 locations in the two study
18 122 transects. All sites were classified into the same land uses and land-use intensity as in the African-wide dataset: primary
19 123 vegetation (39 sites), secondary vegetation (31), plantation forest (27), cropland (69) and urban (14); and within these
20 124 land uses, minimal, light and intense use-intensity. In the analyses, we treated the Kilimanjaro (74 sites) and Taita Hills
21 125 (73 sites) transects as independent field studies owing to their distance from each other (~100km) and different
22 126 geological and evolutionary history.

23 127
24 128 *Environmental and assemblage-structure data*

25 129 We tested whether site-specific variation in land-use intensity, human population density, forest cover and
26 130 metrics describing vegetation greenness and vegetation removal mediate local responses to land use in the independent
27 131 data compared with the African-wide model estimates. We focussed on those variables because previous biodiversity
28 132 models have highlighted their importance for biodiversity (e.g. Newbold et al. 2014a) and because they are readily
29 133 available. We extracted forest cover in the year 2000 (the most recent year for which percent forest cover estimates are
30 134 available at a fine scale) from recently published remote-sensing data at 30-m resolution (Hansen et al. 2013). For
31 135 vegetation greenness and vegetation removal measures, we extracted data from the Moderate Resolution Imaging

Spectroradiometer (MODIS) MOD13Q1 product (the Normalized Difference Vegetation Index; NDVI) at 250-m resolution. Vegetation removal was estimated by calculating the area under the curve of a linear interpolation of NDVI over the three years prior to and including the year of the study following a method first suggested by Tucker et al. (1981), and adjusted for differences in climate seasonality (Newbold et al. 2014a). Mean NDVI over the same time span was used as a measure of average vegetation greenness, to represent continuous gradients of vegetation density not captured by the forest cover dataset. We chose NDVI as our vegetation indicator (rather than, for example, the Enhanced Vegetation Index) for comparability with previous models (Newbold et al. 2014a). For human population, we used Africa-wide high-resolution (100-m) population density (people per km²) estimates for the year 2010 (adjusted to match UN national estimates) from the www.worldpop.org.uk datasets (Linard et al. 2012). Finally, we included local estimates of elevation from the Shuttle Radar Topography Mission (SRTM) at 90-m resolution (Jarvis et al. 2008).

We investigated the range of species' characteristics within assemblages in both the Africa-wide dataset and the independent sites, because these characteristics can influence responses to land use (Owens and Bennett 2000; Flynn et al. 2009; Newbold et al. 2013; De Palma et al. 2015) and thus might mediate the effect of land use on biodiversity locally. Due to the limited coverage and biased data on non-vertebrate species in publicly available databases, we limited this comparison to avian species in both datasets. The analysis was further restricted to records in the assemblage data that were determined to species level (98.4% of records), and matched to scientific names in the catalogue of life (<http://catalogueoflife.org/>, see Hudson et al. 2014). In this analysis we focus on ecological rather than morphological characteristics as for many of the African bird species in our analysis morphological traits are still unavailable. We calculated assemblages' average geographic range size, habitat specialization and IUCN threat status. To estimate range size, we calculated the log-transformed total area of bird species' extent-of-occurrence range maps (Birdlife International 2012), after first converting the range map to a 1° grid and restricting it to the continent of Africa. Range size were log-transformed after visual exploration of the data revealed a strong right-skew of range sizes. The current IUCN threat status for each species was obtained using an automatic query of the IUCN web-api (<http://api.iucnredlist.org/>; accessed 05/11/2014). We grouped all species with threat categories CR (Critically endangered), EN (Endangered) and VU (Vulnerable) as threatened species, and species currently assessed as NT (Near threatened) and LC (Least concern) as non-threatened; species classified as NE (Not evaluated) or DD (Data deficient) were not included further in the analysis. IUCN threat was included owing to its high relevance to policy and decision makers. Finally, we downloaded information on species' habitat preferences from IUCN to assess the percentage of individuals in assemblages that are forest specialists, defined as those species for which any kind of forest habitat is considered to be of major importance. For each site, we calculated, for all occurring bird species: 1) the average log-transformed range size; and the proportion of 2) forest specialist species; and 3) threatened bird species.

167

168 *Data analysis*

169 For each site and dataset, we calculated two biodiversity metrics: species richness as the number of unique observed

170 taxa; and total species abundance as the sum of the abundances of all taxa (corrected where there was varying sampling

171 effort within the published studies, Newbold et al. 2014a). We first modelled the average impact of land use with the

172 African-wide dataset, using generalized linear mixed-effects models (GLMMs: Bolker et al. 2009), with a Gaussian

173 distribution of errors for log-transformed abundance values and a Poisson distribution for species richness. The use of

174 GLMMs was necessary to account for differences among studies (e.g. differences in sampling methods, sampling effort

175 and taxonomic group sampled). These differences were accounted for by including the study identity as a random

176 intercept. We tested if inclusion of taxonomic grouping as a random intercept improved the model (lower Akaike's

177 information criterion – AIC); it did not. We also tested whether two other random terms improved model fit: 1) any

178 spatial block of sampled sites, such as point counts along transects; and 2) land use as a random slope nested within

179 study. For both models, the best random-effects structure (lowest AIC) contained a random slope of land use nested

180 within study, and a random intercept for study identity. Initial models were constructed using the recorded land-use

181 category as a single explanatory variable. Average species richness and total abundance in different land uses in the

182 independent data were then compared with the coefficients of the land-use-only biodiversity model, with

183 correspondence assessed using Z-statistics (Cohen et al. 2013), defined as $Z = \frac{b_{independent} - b_{broad-scale}}{\sqrt{SEb_{independent}^2 + SEb_{broad-scale}^2}}$, where b

184 equals the slope of the modelled effect and SEb its standard error. A z-score is a standardized measurement that

185 quantifies the offset of one value from a normally distributed mean with values smaller than 1.96 generally indicating

186 non-significant deviations (Cohen et al. 2013). Because of study-level methodological differences we could only

187 calculate relative biodiversity values. We used primary vegetation as a baseline for both datasets and calculated the

188 percentage difference in each other land-use category. Some of the differences between the African-wide model and

189 independent data might be because the independent data focused only on birds. To assess the extent to which this was

190 the case, we also developed a African-wide model with the same structure but only containing bird data from the

191 African-wide dataset (1090 sites).

192 To test whether the addition of more environmental information than just land use could improve the

193 correspondence between the independent data and the African-wide biodiversity model, we developed a second set of

194 GLMMs of species richness and total abundance using the African-wide dataset. In these models we again fitted land

195 use, but this time also land-use intensity (including in interaction with land use) and all continuous environmental

196 variables (see above). We subjected this model to a model-selection process, by fitting models with all possible additive

combinations of explanatory variables and selecting the model with the lowest AIC value. The goodness of fit (AIC and R^2 , assessed against the model-training data) of the new model and the land-use-only model were compared, and we assessed the importance of the included covariates by summing the AIC weights of all models containing each variable (Burnham & Anderson, 2002). To assess the change in correspondence with the independent data both the best-performing model and a land-use-only model were used to predict abundance and species richness at the independent field-study sites, using the environmental variables.

We tested the residuals of both the land-use-only and the overall best-fitting model for spatial autocorrelation using a Moran's I test. None of the individual studies showed significant autocorrelation within our models (SI Figure 2). All analyses were performed in R (ver. 3.2.2, R Core Team 2014) mainly using lme4 (ver. 1.10, Bolker et al. 2009; Bates et al. 2014) for model fitting, AICcmodavg for model selection (ver. 2.0.3, Mazerolle 2015), spdep for spatial autocorrelation tests (ver. 0.5-88, Bivand and Piras 2015) and MODISTools (ver. 0.94.6, Tuck et al. 2014) for obtaining NDVI data.

Results

Responses to land use of both biodiversity metrics were largely consistent between the modelled African-wide estimates and the independent data, although there were large discrepancies for some land uses (Figure 2; log-abundance: median absolute $Z = 0.991$, range = 0.06 – 5.76, species richness: median absolute $Z = 0.728$, range = 0.037 – 2.877). The biggest discrepancy between the independent data and the African-wide biodiversity model was for cropland sites: the independent sites (especially in the Taita Hills transect) had much higher total abundance and species richness than predicted from the Africa-wide dataset (Figure 2). This discrepancy became smaller for abundance if the African-wide model was based only on bird data, but this was not the case for the species richness model (SI Figure 3). There was large uncertainty around the means, especially in the African-wide dataset, reflecting a wide range of responses among different studies (SI Figure 1).

There were considerable differences in local environmental conditions between the Africa-wide and independent field datasets (Figure 3). Mean vegetation greenness (NDVI) of independent sites in primary vegetation, secondary vegetation and plantation forest were lower than the average African site, whereas the opposite was true for cropland and urban sites in the Taita Hills. Forest cover was higher in primary vegetation and cropland at sites on both independent transects. Independent sites had a higher human population density than the average African sites in all land-use categories, especially urban sites, which had up to 2.5 to 4 times higher density than the African-wide average (Figure 3).

The full model based on the African-wide dataset, and including all environmental variables as explanatory variables, showed a better fit to the data for both total abundance ($\Delta AIC = 1591.91$, $\Delta r^2_{GLMM} = 0.08$) and species richness ($\Delta AIC = 4562.48$, $\Delta r^2_{GLMM} = 0.02$). However, these models still only explained a low proportion of the observed variation in total abundance (marginal $r^2_{GLMM} = 0.09$) and species richness ($r^2_{GLMM} = 0.03$). Across all candidate models, land use, land-use intensity, their interaction, and vegetation removal were of the greatest relative importance for explaining abundance and species richness (for each of these variables, summed AIC weights, $\sum AIC_w \approx 1$). Human population density was of high importance for species richness ($\sum AIC_w \approx 1$), but less important for abundance ($\sum AIC_w = 0.589$). Mean vegetation greenness of the three years before the sampling was more important for abundance ($\sum AIC_w = 0.944$) than for species richness ($\sum AIC_w = 0.506$). Elevation was not selected among the explanatory variables in the best model, and was of lower importance for both species richness ($\sum AIC_w = 0.270$) and abundance ($\sum AIC_w = 0.316$). Furthermore, elevation did not show a significant correlation with species richness ($p > 0.05$) at the independent field sites. However the abundance of bird species in the Taita Hills decreased significantly with increasing elevation ($P < 0.001$, Figure S4-B). We found the difference between model-predicted values and observed values in the independent data to be quite mixed depending on the model used, the biodiversity metric considered, and the land use in question (Figure 4). For abundance the land-use-only model (average absolute difference = 19.81%) performed slightly worse in predicting relative abundance compared to the best selected model (average absolute difference = 18.83%), while for species richness the land-use-only model predictions were closer to the observed (average absolute difference = 15.47%) than those from the best selected model (average absolute difference = 27.44%). A notable exception was cropland, for which the predictions made by the full model with all environmental factors were substantially better than those made by the land-use only model (Figure 4).

Bird species at our independent sites were on average more wide-ranged species compared to bird species at sites in the African-wide dataset (Figure 5), with the exception of primary forests in the Taita Hills, where significantly more narrow-ranged species were found. Sites in the independent dataset had similar or lower proportions of forest specialist species than the sites in the African-wide dataset, with the exception of primary vegetation and cropland in the Taita Hills where the proportion of forest specialist birds was higher (Figure 5). Our independent sites had similar proportions of threatened bird species as the average site in the African-wide dataset, but higher proportions in primary vegetation in the Taita Hills study area (Figure 5).

Discussion

Our results show that independently observed local biodiversity responses to land use are mostly consistent with an African-wide model estimates. While species richness consistently declines with increasing levels of human land use in most cases (Figure 2), the total abundance stays fairly stable. However, the African-wide model showed that responses to land use vary substantially among different studies (Figure S1); this heterogeneity is especially apparent in urban sites, perhaps because local factors, such as vegetation greenness and proximity to nearby forests, mediate responses. It should be noted however that there are only few urban studies in Africa in the database, indicating that there is a need for further research on the effect of urbanization on biodiversity in this continent. We could not detect any influence of elevation on species richness in either of our independent sites or the African-wide dataset. However, bird abundance decreased with elevation in the Taita Hills, which could be explained by the fact that the low elevation areas receive many nutrients and water, thus increasing resources and diversity of land cover available for many bird species. Similarity of species composition decreased with increasing elevational distance between sites (Figure S4-C), thus indicating a turnover of species assemblages with elevation. Land use has likely added to this effect and might have altered the natural elevational gradient in species richness (McCain 2009). The interaction between elevation and land use however could not be tested with confidence as land use in both study transects is not spread equally across elevations (Figure S4-D). In particular, primary vegetation sites are significantly higher in elevation than other land uses (see next section for possible implications of this for the results). The biggest discrepancy between the biodiversity estimates was for cropland: the independent data had higher values of both biodiversity metrics than predicted from the Africa-wide dataset. This might partly reflect the fact that the field survey sampled only birds: bird-only models of the African-wide datasets decreased the mismatch within cropland, at least for abundance (SI Figure 3). Previous research has shown that taxonomic groups can show different responses to land use (Lawton et al. 1998; Schulze et al. 2004; Newbold et al. 2014a). Birds are highly mobile species, often dependent on various habitats in the surrounding landscape (Haslem and Bennett 2008) and show seasonal fluctuations of activity. Therefore our independent field data will reflect neither the whole assemblage present in the study area nor the general effect of land use on biodiversity. The discrepancy emphasizes the need to collect field data for a set of taxonomic groups that are as representative as possible. In addition to real taxonomic differences in responses to land use, it is likely also that surveying of different taxonomic groups is done at different spatial scales, which could also cause apparent differences in responses among taxa (note however that a previous study using the same dataset found little effect of sampling scale on relative differences in diversity among land uses; Newbold et al. 2015). On the other hand, the African-wide model omits several aspects of the local environmental and ecological conditions, which we discuss in the following sections.

Impoverished species pool

1 287 One explanation for the difference in biodiversity between cropland sites on the Taita Hills and the average
2
3 288 cropland site in the Africa-wide model could be that the primary vegetation in Taita Hills has already suffered more
4
5 289 biodiversity loss than the average primary-vegetation site in the African-wide dataset. The Taita Hills have a high
6
7 290 degree of habitat fragmentation and the lowest overall forest cover in all of the Eastern Arc Mountains (Newmark 1998;
8
9 291 Platts et al. 2011), reflecting the long history of human modification and disturbance in the area (Newmark 1998;
10
11 292 Brooks et al. 1998; Heckmann et al. 2014). Such conditions might have influenced the response of species richness to
12
13 293 land use by leaving assemblages that are impoverished and relatively insensitive to further land-use disturbance
14
15 294 (Filippi-Codaccioni et al. 2010); the resulting biota might also show different associations between species
16
17 295 characteristics and sensitivity than seen in newly impacted regions (Fritz et al. 2009).

18
19 296 The greater Kilimanjaro area and the Taita Hills have been used by humans for many centuries (Heckmann et
20
21 297 al. 2014). Expeditions undertaken by German missionaries visiting Mount Kilimanjaro noted that the land was already
22
23 298 extensively used in the 19th century (Börjeson 2009) and similar evidence suggests that the agricultural terraces of the
24
25 299 Taita Hills are centuries old (Conte 2010). These sources indicate that both landscapes have experienced human
26
27 300 influence for many centuries. The loss of natural vegetation seems to have accelerated in the last century owing to
28
29 301 increasing human population density, colonial forestry operations (Brooks et al. 1998; Hemp 2005; Burgess et al.
30
31 302 2007b; Platts et al. 2011) and the ongoing shift from traditional forms of crop cultivation to monoculture farming (Soini
32
33 303 2005; Hemp 2006b). Biodiversity models would benefit from incorporating estimates of land-use history, but the
34
35 304 currently available data (e.g. Klein Goldewijk et al. 2011) are too coarsely resolved to be very useful.

36
37 305 Our study sites had on average a similar proportion of forest-dependent species in primary vegetation, but a
38
39 306 smaller proportion in plantation forest sites than in the African-wide dataset (Figure 5). However, the average number of
40
41 307 narrow-ranged and threatened bird species was higher on the Taita Hills compared to sites across Africa, which reflects
42
43 308 the high conservation value of large continuous forest in this global biodiversity hotspot (Burgess et al. 2007b), and
44
45 309 suggests that not all sensitive species have yet been lost from assemblages at the Taita Hills. It has been suggested that
46
47 310 plantation forests could support conservation efforts if appropriately managed (Brockerhoff et al. 2008). However, this
48
49 311 does not seem to be the case for our field sites: plantation forests, such as *Eucalyptus*, pine and *Cypress* stands on Taita
50
51 312 Hills had lower abundance and species richness than either primary or secondary vegetation (Figure 2), emphasizing the
52
53 313 importance of natural vegetation for local biodiversity conservation (Brooks et al. 1998; Farwig et al. 2008; Gibson et
54
55 314 al. 2011). Overall, our results support evidence (Owens and Bennett 2000; Flynn et al. 2009; Newbold et al. 2013; De
56
57 315 Palma et al. 2015) that accounting for functional characteristics can add precision to African-wide biodiversity models
58
59 316 for certain well-studied taxonomic groups.

It is also possible that the species pool appears impoverished because the reference primary vegetation sites were located at high elevations, which are probably less diverse naturally. However, this is unlikely to explain our results entirely for three reasons. First, cropland had relatively high biodiversity even when compared with secondary vegetation, which like cropland was found at lower elevations in our field study areas. Second, other human land uses didn't have as high biodiversity as cropland despite also being found at low elevations. Third, the observed mismatch in biodiversity in croplands can be best explained by the occurrence of low-intensity agroforestry systems (known locally as 'homegardens'), which were located at higher elevations than more intensively used croplands.

High-diversity cropland

Cropland sites in our independent dataset had relatively high diversity and a possible reason could be the management mode, since the majority of these sites were tropical agroforestry systems known locally as 'homegardens', which occur in mid-high elevational ranges. Tropical homegardens, such as the Chagga homegardens on Kilimanjaro, have many biodiversity-beneficial characteristics of agroforestry systems such as higher indigenous tree density and permanent or semi-permanent cultivation cycles, thus ensuring consistent vegetation cover and provision of valuable microhabitats (Hemp 2006a; Scales and Marsden 2008; Jose 2009). They can thus contribute to the persistence of species in human-modified landscapes (Bhagwat et al. 2008; Kabir and Webb 2008; Gardner et al. 2009), a conclusion which our study supports. The landscape context and proximity to nearby remaining forest fragments could also have led to an increase in species richness.

We show that the cropland sites in our independent dataset have slightly higher forest cover and mean vegetation greenness than the typical cropland site in Africa (Figure 3). These environmental factors might help explain the discrepancies in estimated avian diversity, and led to better predictions of bird diversity in croplands when included in the models (Figure 4). We suggest that more research on broad-scale environmental variables that are locally relevant is needed to improve models of biodiversity responses to land use. In addition to differences in environmental variables, along both independent study transects, cropland sites were composed of slightly more forest-dependent species than the average cropland site in Africa, showing that the local environmental features of cropland are associated with retention of at least some forest species. We suggest that agricultural management practices and land-use dynamics are important factors to consider in biodiversity models, either by considering the intensity of human land use (Newbold et al. 2015), explicitly recognising agroforestry as distinct land-use type (Alkemade et al. 2009), or by including remote-sensed information on vegetation greenness or tree cover in cropland (Pettorelli et al. 2005; Hansen et al. 2013; Newbold et al. 2014a).

347

348 **Conclusion**

349 We identified important local factors that mediate biodiversity's response to land use. Biodiversity models
350 might be inaccurate if used to predict land-use impacts on biodiversity at local scales if local conditions do not conform
351 to the average conditions seen in the African-wide dataset. This highlights the importance of local surveys that identify
352 the local conditions and influencing variables before applying generalized biodiversity models in a local context. On the
353 other hand, field data sets need to consider a wide, representative set of taxa in order to be representative of
354 biodiversity's response to land use. The inclusion of local land management information, vegetation data from remote
355 sensing, and species characteristics information can make biodiversity models more applicable to local settings.
356 However more research is needed to identify which variables are locally relevant.
357

358 **Acknowledgements**

359 We thank all PREDICTS data contributors for their biodiversity data, which was collated using support from the Natural
360 Environment Research Council (NERC, grant number: NE/J011193/2). Furthermore we would like to thank the Climate
361 Change Impacts on Ecosystem Services and Food Security in Eastern Africa (CHIESA) project (<http://chiesa.icipe.org>)
362 for support of the conducted fieldwork. TN was also supported by a Leverhulme Trust Research Project grant. The
363 biodiversity survey of birds on the independent sites has also been supported by the Danish International Development
364 Agency (DANIDA) in form of a travel grant given to MJ (grant no. A26811). We would furthermore like to thank two
365 anonymous reviewers, who have helped to improve the manuscript. The independent field data is available on request
366 from the authors. This is a contribution from the Imperial College Grand Challenges in Ecosystem and the Environment
367 Initiative. PREDICTS is endorsed by the GEO BON.

Table 1: Best-fit model from among those using all possible combinations of explanatory variables for the African-wide dataset. Pseudo-R² values were computed following (Nakagawa and Schielzeth 2013).

Model terms	Model	K	AIC	Δ AIC	LogLik	DF (resid)	R ² (marginal)	R ² (conditional)
Land use*Land use intensity + log(Population density) + Vegetation removal + mean Vegetation greenness	log-Abundance	34	3844.27	0	-1888.13	1515	0.088	0.876
Land use ~1		22	5436.18	1591.91	-2696.09	2224	0.009	0.879
Land use * Land use intensity + log(Population density) + Vegetation removal + Forest cover + mean Vegetation greenness	Species richness	35	10920.67	0	-5425.34	1984	0.034	0.926
Land use ~1		22	15483.15	4562.48	-7719.58	2834	0.013	0.919
		18	15484.08	4563.41	-7724.04			

Figure 2: The response of species richness and total abundance to land use, from the Africa-wide model and the independent field data. Land-use categories are primary vegetation (PV), secondary vegetation (SV), plantation forest (PL), cropland (CL) and urban (UR). All coefficients are visualized as proportional difference to primary vegetation (PV), which was set at a baseline of 100%. Error bars show one standard error. Labels on top show the Z-statistic, which quantifies the distance between the independent data and the African-wide modelled estimates, taking into account the uncertainty in both cases. Z-statistics further from zero indicate greater mismatch.

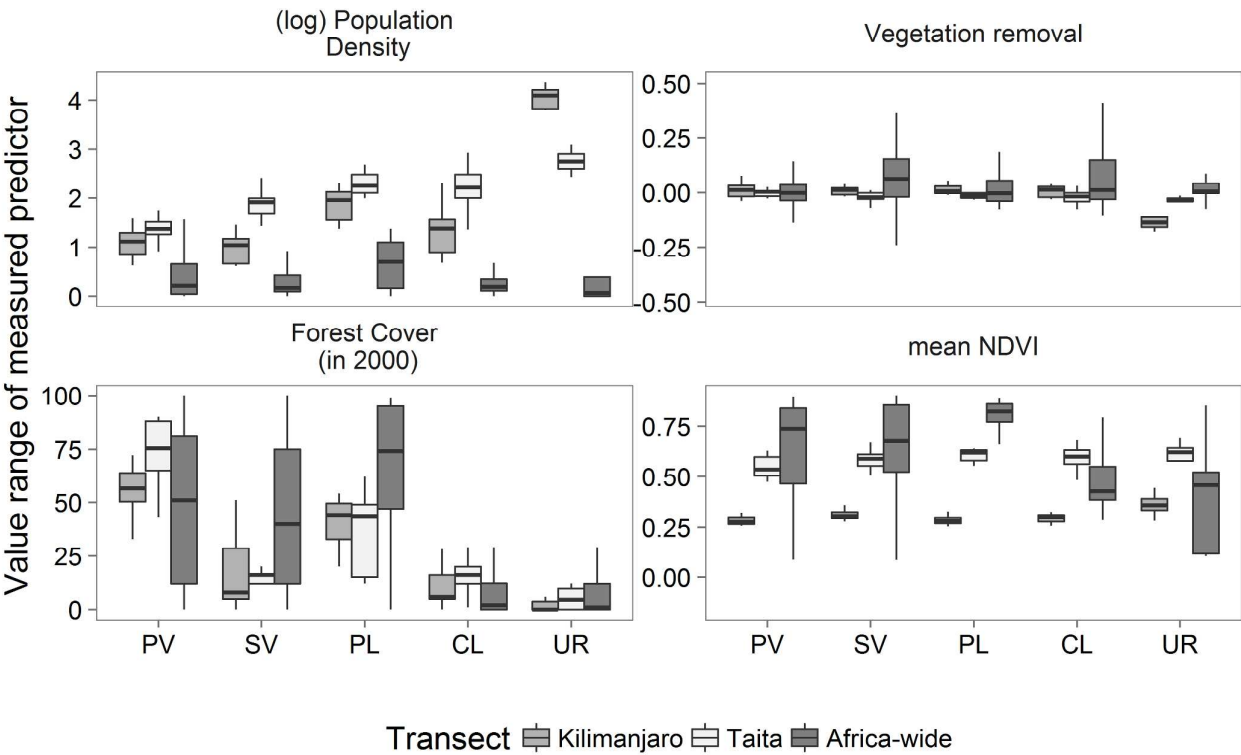

Figure 3: Difference in environmental variables in different land uses, between the Africa-wide and the independent field data ('Kilimanjaro' and 'Taita'). Boxes show the inter-quartile range, while lines show the full range of the data (or 1.5 times the upper and lower quartiles if less extreme). Abbreviations as in Figure 2.

Figure 4: Difference between the relative observed biodiversity values at the field sites, and predicted biodiversity values from the best-selected model and a land-use-only model (see Table 1). Predicted values were obtained by applying the models to the estimated environmental covariates at the field study sites. The predicted model estimates were subtracted from the observed field values. Thus, positive values indicate a model predicting lower biodiversity than was observed with overall smaller bars indicating better fit to the observed. Primary vegetation was used as the baseline and abbreviations are as in Figure 2.

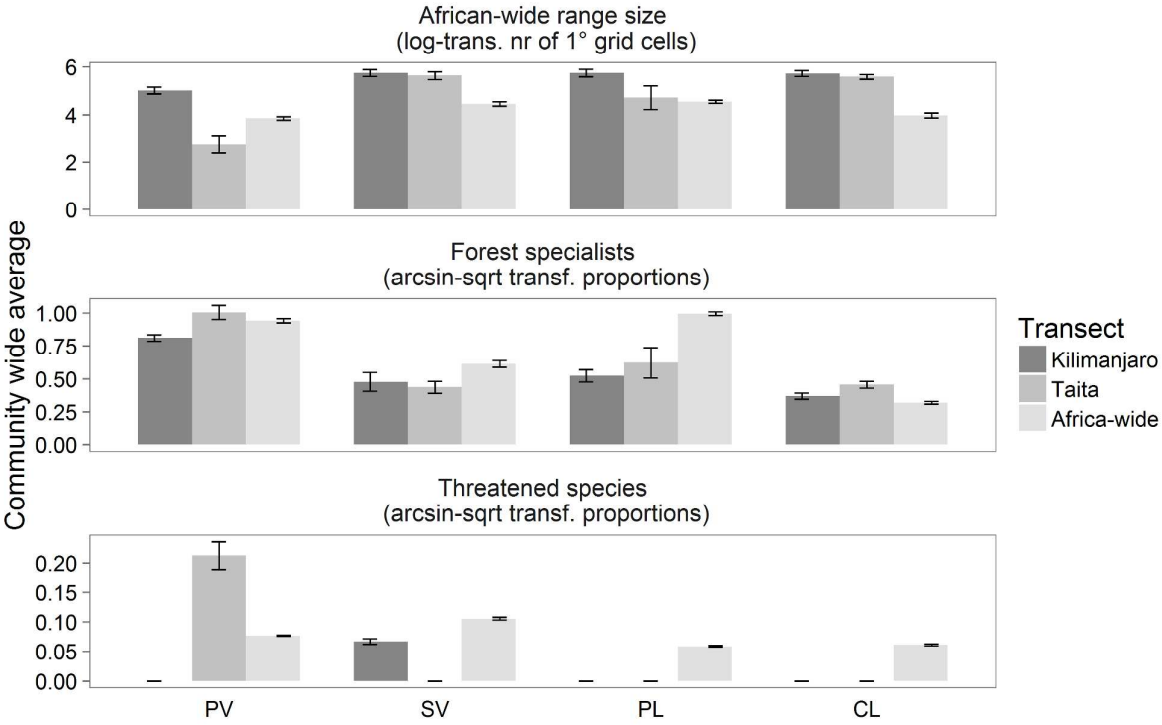

Figure 5: Average assemblage structure in terms of bird species' characteristics, for the Africa-wide and the independent ('Taita' and 'Kilimanjaro') datasets, in different land uses. Range size was measured as the average (log-transformed) extent of occurrence across Africa of all bird species recorded at each site, forest specialism was classified based on the IUCN classification of habitat preference, and threat status was from the IUCN Red List (species classified as critically endangered, endangered or vulnerable were considered to be 'threatened'). For each sites, we calculated the average proportions of species classified as forest specialist or as threatened. Proportions of forest specialist and threatened species was arcsin-squareroot transformed to better highlight differences. Error bars show the standard error of the mean.

Supporting information

Figure S1: For the broad-scale dataset (black points) and the field sites (coloured points), the relative species richness and abundance values (compared to primary vegetation as a baseline) of all land uses for each individual study. The figure shows that our field-study estimates are always within the range of modelled study-level estimates in the broad-scale dataset. Land-use categories are primary vegetation (PV), secondary vegetation (SV), plantation forest (PL), cropland (CL) and urban (UR).

Table S1: Full list and description of studies in the broad-scale dataset. Studies that looked at multiple taxonomic groups were split into individual studies for the analysis.

Figure S2: Tests for spatial autocorrelation within the model residuals, showing the distribution of P-values from sets of Moran's tests on the residuals associated with each individual study. Significant autocorrelation ($P < 0.05$) is indicated by the vertical red line.

Figure S3: The response of species richness and total abundance to land use, from the Africa-wide model (open symbols) and the independent field data for cropland (closed symbols). Here, the Africa-wide models are shown for all taxonomic groups (open circles) and for birds only (open triangles). Land-use categories are primary vegetation (PV), secondary vegetation (SV), plantation forest (PL) and cropland (CL). There is no urban category (UR) for comparison as there were insufficient numbers of urban sites in the broad scale dataset for birds. All values are expressed as the percentage of the baseline values in primary vegetation. Error bars show one standard error.

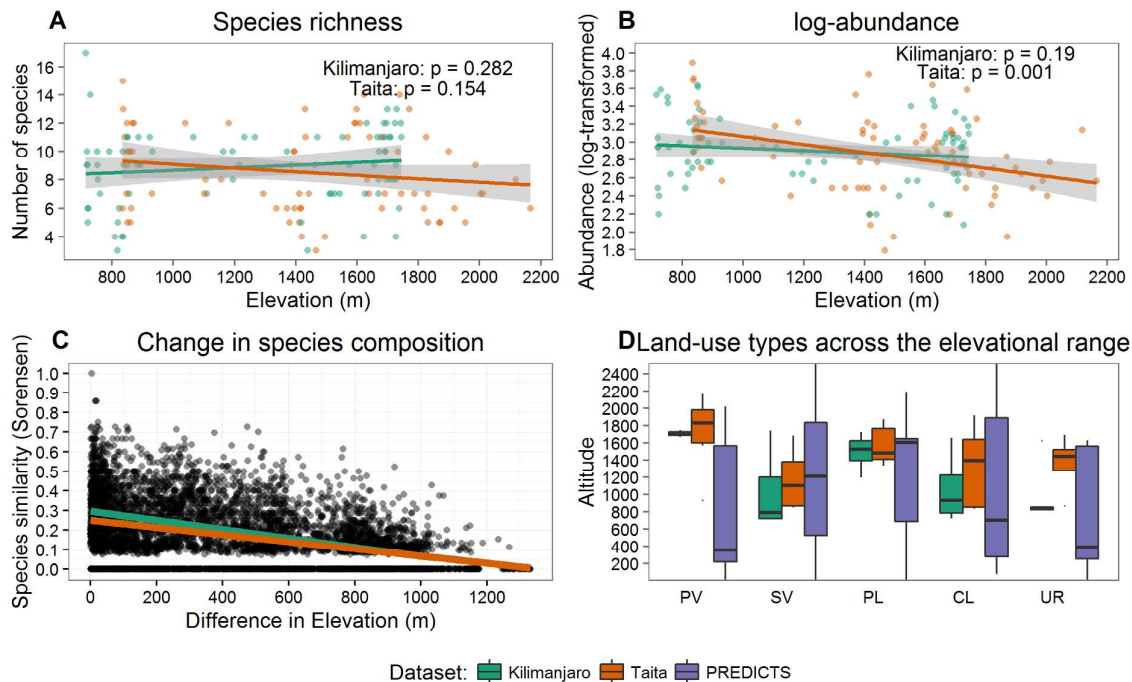

Figure S4: Effect of elevation (in m) on species richness, log-abundance and species composition for our independent field sites at Taita and Kilimanjaro. Generalized linear model with Poisson errors (for Species richness) and Gaussian errors (for log-abundance) were fitted independently for each transect. Changes in composition were assessed as Sørensen similarity index between all pairs of sites and fitted against the absolute difference in elevation between sites using generalized linear models with Gaussian errors. (A) There was no significant effect of elevation on species richness for either transect, but there was a significant effect for log-abundance in the Taita Hills (B). (C) Species assemblage similarity decreases with elevational differences between sites. (D) Distribution of the land-use classes of our independent sites across the elevational range of both study transects. Land use abbreviations as in Figure S1.

Table S2: The PREDICTS project (Hudson et al., 2014, www.predicts.org.uk) land use and land-use intensity matrix to which all study sites have been classified.

	Minimal use	Light use	Intense use
Primary forest (forest composed of native vegetation, which is not known to have been destroyed during historical times)	Any threats identified are very minor (e.g., very light use) or very limited in the scope of their effect (e.g., hunting of a particular species of limited ecological importance).	One or more threats of moderate intensity (e.g., selective logging) or breadth of impact (e.g., bushmeat extraction), which are not severe enough to markedly change the nature of the ecosystem.	One or more threats that is severe enough to markedly change the nature of the ecosystem (e.g., clear-felling).
Primary Non-Forest (native vegetation, which has not been destroyed recently enough for there to be any discernible impact on vegetation architecture)	Any threats identified are very minor (e.g., very light use) or very limited in the scope of their effect (e.g., hunting of a particular species of limited ecological importance).	One or more threats of moderate intensity (e.g., selective logging) or breadth of impact (e.g., bushmeat extraction), which are not severe enough to markedly change the nature of the ecosystem.	One or more threats that is severe enough to markedly change the nature of the ecosystem (e.g., clear-felling).
Mature Secondary Vegetation (previously destroyed vegetation recovering to natural state rather than being managed to maintain it in a non-natural state; architecture, if not diversity, approaching original complexity)	As for Primary Vegetation-Minimal use	As for Primary Vegetation-Light use	As for Primary Vegetation-Intense use
Intermediate Secondary Vegetation (previously destroyed vegetation recovering to natural state rather than being managed to maintain it in a non-natural state; mixed architecture or mid-successional stage of recovery)	As for Primary Vegetation-Minimal use	As for Primary Vegetation-Light use	As for Primary Vegetation-Intense use
Young Secondary Vegetation (previously destroyed vegetation recovering	As for Primary Vegetation-Minimal use	As for Primary Vegetation-Light use	As for Primary Vegetation-Intense use

to natural state rather than being managed to maintain it in a non-natural state; mainly ruderal species and simple architecture; early-successional stage)			
Secondary Vegetation (indeterminate age) (previously destroyed vegetation recovering to natural state rather than being managed to maintain it in a non-natural state; age indeterminate)	As for Primary Vegetation-Minimal use	As for Primary Vegetation-Light use	As for Primary Vegetation-Intense use
Plantation forest	Extensively managed or mixed timber, fruit/coffee, oil-palm or rubber plantations in which native understorey and/or other native tree species are tolerated, which are not treated with pesticide or fertiliser, and which are not clear-felled.	Monoculture fruit/coffee/rubber plantations with limited pesticide input, or mixed species plantations with significant inputs. Monoculture timber plantations of mixed age with no clear-felling. Monoculture oil-palm plantations with no clear-felling.	Monoculture fruit/coffee/rubber plantations with significant pesticide input. Monoculture timber plantations with similarly aged trees or timber/oil-palm plantations with extensive clear-felling.
Cropland	Low-intensity farms, typically with small fields, mixed crops, crop rotation, little or no inorganic fertiliser use, little or no pesticide use, little or no ploughing, little or no irrigation, little or no mechanisation.	Medium intensity farming, typically showing some but not many of the following: large fields, annual ploughing, inorganic fertiliser application, pesticide application, irrigation, no crop rotation, mechanisation, monoculture crop. Organic farms in developed countries often fall within this category, as may high-intensity farming in developing countries.	High-intensity monoculture farming, typically showing many of the following features: large fields, annual ploughing, inorganic fertiliser application, pesticide application, irrigation, mechanisation, no crop rotation.
Pasture	Pasture with minimal input of fertiliser and pesticide, and with low stock density	Pasture either with significant input of fertiliser or pesticide, or with high stock density	Pasture with significant input of fertiliser or pesticide, <i>and</i> with high stock density (high enough to cause significant

	(<i>not</i> high enough to cause significant disturbance or to stop regeneration of vegetation).	(high enough to cause significant disturbance or to stop regeneration of vegetation).	disturbance or to stop regeneration of vegetation).
Urban	Extensive managed green spaces; villages.	Suburban (e.g. gardens), or small managed green spaces in cities.	Fully urban with no significant green spaces.

Table S3: Full model selection table for (log-transformed) abundance. All possible combinations of land use (PREDICTS.LU), land-use intensity (PREDICTS.LUI) Land use/Land-use intensity interaction (LUInter), log-transformed human population density (logpop), forest cover (FC2000), elevation (elev), mean NDVI (meanNDVI) and vegetation offtake (yield.ndvi.corr) were fitted. Shown are the model covariates, the parameter count (K), AIC, delta AIC, the Model likelihood (ModelLik), AIC weights (AICWt), log-likelihood (LL) and cumulative AIC weights (Cum.Wt). ModelLik and AICwt are rounded to the fifth decimal for visual display.

Table S4: Full model selection table for species richness. All possible combinations of land use (PREDICTS.LU), land-use intensity (PREDICTS.LUI) Land use/Land-use intensity interaction (LUInter), log-transformed human population density (logpop), forest cover (FC2000), elevation (elev), mean NDVI (meanNDVI) and vegetation offtake (yield.ndvi.corr) were fitted. Shown are the model covariates, the parameter count (K), AIC, delta AIC, the model likelihood (ModelLik), AIC weights, log-likelihood (LL) and cumulative AIC weights (Cum.Wt). ModelLik and AICwt are rounded to the fifth decimal for visual display

Model covariates	K	AIC	Delta AIC	ModelLik	AICWt	LL	Cum.Wt
